# ABSTRACT

## **EXCHANGE RATE PASS-AROUND\***

*Matthieu Crozet, Julian Hinz, and Federico Trionfetti*

In January 2015, The Swiss Franc (CHF) appreciated unexpectedly against the Euro by approximately 15%. We document a new fact: French firms that exported to both the Swiss market and the Eurozone also exhibited a sudden change in their export prices to the Eurozone. We coin this the “exchange rate pass-around” effect. We rationalise this fact with a simple model based on the endogenous decision of some firms to give up pricing-to-market and opt for single-pricing to all markets. An important implication of this finding is that single-pricing may be one of the causes of the incomplete pass-through. This mechanism has so far remained unexplored in the literature, which may have led to overestimating the importance of other factors. Based on monthly French export data, our empirical analysis confirms the existence of the pass-around. Firms directly affected by the CHF exchange rate shock increased their prices in neighboring markets by 0.8% compared to other exporters. The effect was stronger for firms with lower ex-ante price heterogeneity across markets and for firms with smaller trade costs to Switzerland. However, the effect was short-lived. As time passed, exporters tended to decouple the prices they set on the Swiss market from those for the Eurozone, and the pass-around effect faded.

# 1 Introduction

On January 15, 2015, at exactly 10:30 local time, the Swiss National Bank (SNB) abandoned the ceiling constraining the exchange rate to a maximum of 0.833 Euro (EUR) per Swiss Franc (CHF), that is 1.20 CHF for 1 EUR. Within seconds, the Swiss currency reached a record level of less than one Swiss Franc to the Euro before stabilizing at around 0.96 Euro to the Franc in June 2015 and then at about 0.92 by the end of 2015. Figure 1 shows that the shock was substantial, sudden (see the jump of the spot rate), unanticipated (the forward rates the day before the shock were absolutely flat), and expected to be irreversible (the forward rates after the shock track very closely the spot rate).

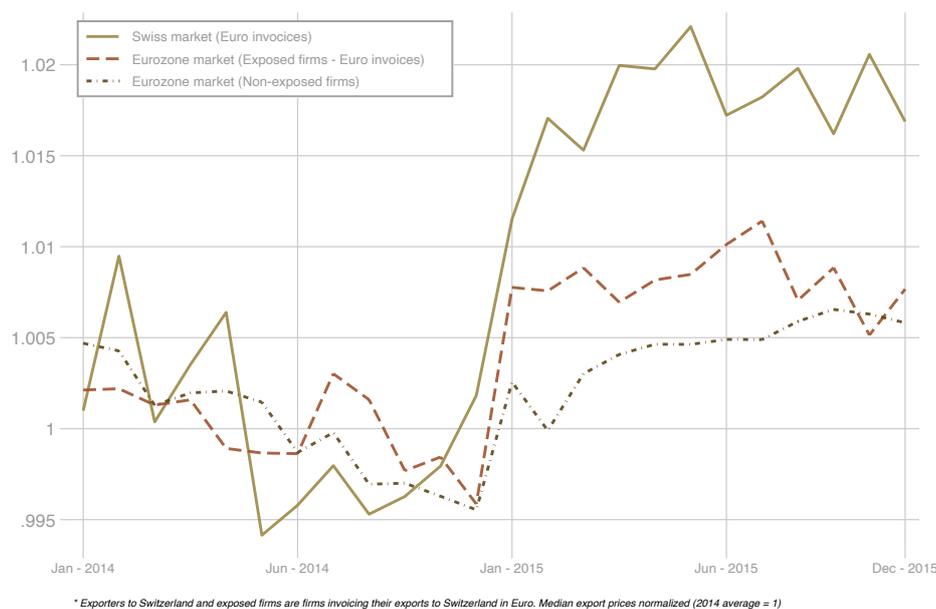

**Figure 1:** Spot and forward rates: EUR/CHF

Like a number of recent works, we use this exceptionally clear shock to identify a specific exchange rate-induced mechanism of trade price changes. One set of papers related to ours studies the immediate price effects associated to the CHF shock. For instance, Bonadio et al. (2020) investigate the speed of the adjustment, finding fast adjusting pass-through. Auer et al. (2021) find the pass-through differs by invoicing currency (and disappears over time), affecting consumer prices and allocations. Freitag and Lein (2023) find that increased product quality explains part of the pass-through into export prices. Auer et al. (2019), and Kaufmann and Renkin (2019) explore how the price response differs depending on whether trade flows are invoiced in euros or in Swiss francs.<sup>1</sup>

Instead of focusing on the consequences of exchange rate shocks on the firms and trade flows of the countries directly concerned, we unveil a new empirical fact: The repercussions of an

<sup>1</sup>Other studies focus on the influence of this shock on the behaviour of consumers (Auer et al., 2022; Burstein et al., 2022), or that of firms (see Efing et al. (2022), Kaiser et al. (2018), and Arni et al. (2023) for studies exploring the shock's impact on investments, R&D, and employment).

**Figure 2: Exchange rate pass-around**

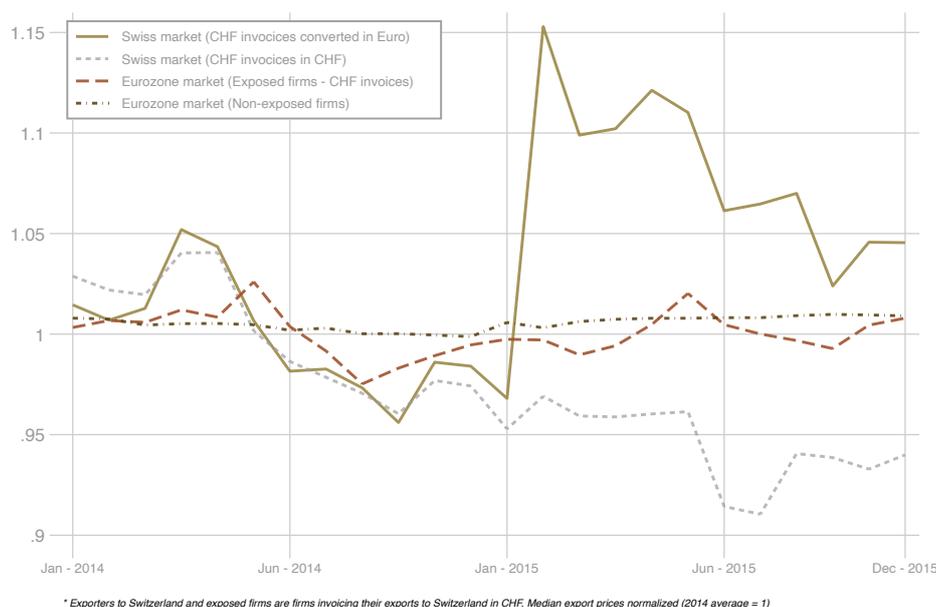

exchange rate shock on export prices to *third countries*. We name this novel empirical finding the *Exchange Rate Pass-Around (ERPA)*. *Prima facie* evidence of the ERPA is provided by Figure 2. The figure shows the adjustment of French export prices to Switzerland and to the Eurozone in the months before and after the appreciation of the Swiss Franc.<sup>2</sup> Some exporters set prices in Euro to every destination while some other exporters set prices in the currency of destination. To avoid pollution from reconverting data to Euro, Figure 2 is constructed using data for firms exporting in Euro to all destination. In this group of firms there are firms that export to Switzerland and to the Eurozone (the exposed firms) and firms that export to the Eurozone but not to Switzerland (non-exposed firms). Fig. 2 shows that exposed firms have increased their export prices to Switzerland *and* to the Eurozone relative to non-exposed firms (solid and dashed lines relative to dash-dotted line). This is the exchange rate pass-around: the price adjustment does not only concern the export price *vis-à-vis* the country whose exchange rate has changed but also *vis-à-vis* third countries. This fact points at some inability or unwillingness to price discriminate between markets. Not all firms behave the same, however. Figure 3 shows the price reaction of firms that invoice in Swiss Francs.

The pass-around is zero for these firms, as revealed by the fact that the price to the Eurozone of these firms is essentially indistinguishable from that of non-exposed firms. The grey dotted line and the continuous olive-color line track the changes to, respectively, the price paid by Swiss consumers and its re-conversion to Euro operated by French Customs.

Unveiling the pass-around is not only interesting in its own right. It is also suggestive of a new interpretation for the often observed partial exchange rate pass-through (ERPT). Firms

<sup>2</sup>The graph shows the median of the standardized prices. The latter are the residuals of a regression of the log of prices on firm-product, product-month and country-month fixed effects.

**Figure 3: Exchange rate pass-through**

that export to Switzerland in Euro have increased their export prices (which implies a partial ERPT). If we did not know about the ERPA we would tend to attribute the partial pass-through to variable mark-up or to marginal costs paid partially in foreign currency (see, e.g., Corsetti and Dedola (2005), Berman et al. (2012)). Awareness of the ERPA pushes instead towards a different rationalisation: the inability or unwillingness of some firms to price discriminate between countries. In such case a single price has to capture features of all markets. Therefore, an exchange rate shock induces a change in the export price to all destinations which, necessarily, implies a partial ERPT. The ERPA also helps understand other well documented facts. The first one is that the extent of the ERPT depends on the currency of invoice see, e.g., Auer et al. (2021), Auer et al. (2019), Bonadio et al. (2020) for recent evidence from Swiss firms, and Corsetti et al. (2022) for British firms.<sup>3</sup> This fact is well documented but never explored theoretically. We show that it can be explained by the inability or unwillingness to price discriminate if firms that are unable or unwilling to price discriminate are also unable to invoice in different currencies; and perhaps for the same reason related to the fix costs that such price discrimination and multi-currency invoicing involves. In this view, it is not currency *per se* that matters for the ERPT but, instead, is the ability or willingness to price discriminate between markets. The second fact is that the magnitude of the ERPT depends on firm size. This fact is well documented in Berman et al. (2012) and in Devereux et al. (2017)<sup>4</sup> and may also be explained by low ability of small firms to price to the market. This hypothesis is corroborated by the empirical literature that finds a wide heterogeneity in price discrimination behaviors. For instance, Fontaine et al. (2020) study the cross-sectional dispersion of prices paid by EMU importers for French products. They find

<sup>3</sup>The latter describes trends in exports prices after the 2016 devaluation of the pound very similar to the ones shown in figures 2 and 3.

<sup>4</sup>Devereux et al. (2017) find that both the magnitude of the pass-through and the choice of the invoicing currency are linked to firm size. Very small and very large exporters have higher rates of pass-through and tend to invoice in the foreign currency.

that price discrimination between markets is more pronounced among the largest firms and for more differentiated products.

The incompleteness of ERPT depicted in Panel 2 and confirmed by our empirical analysis is in line with most of the literature; see, e.g., Goldberg and Knetter (1996), Campa and Goldberg (2004), Gopinath and Rigobon (2008), Gopinath et al. (2010), Fontagné et al. (2018), and Freitag and Lein (2023), or Burstein and Gopinath (2014) for a review. Differently from this literature we provide a rationale — the inability to price discriminate between markets — that explains the ERPT and the ERPA. Some papers have found that the incompleteness of the ERPT may be attributed to flexible markup, see e.g., Atkeson and Burstein (2008), Berman et al. (2012), Garetto (2016), Amiti et al. (2019), Amiti et al. (2020), Mayer and Steingress (2020). Our empirical evidence is compatible with these results but we also find that a large part of the incomplete pass-through may be explained by the inability or unwillingness to price discrimination rather than by flexible markup mechanisms. Our explanation has the advantage of being consistent with partial exchange rate pass-through as well as with the exchange rate pass-around effect observed in the data and depicted in Figure 2 and 3. Flexible markup alone, instead, does not immediately explain the pass-around.

Our paper makes six main points. First, we provide a new explanation for the incomplete pass-through. While most of the existing literature tends to conclude that the pass-through is smaller the more firms have the ability to price-to-market, we show that it is also possible that incomplete pass-through results instead from firms being *less* able to price-to-market. Second, the single-pricing mechanism we propose in our model may be fruitfully employed to better understand price dynamics after a variety of shocks, such as cost shocks (e.g. surge of energy prices or fiscal stimuli) or trade shocks. Third, the price repercussions on third markets suggest a useful distinction between vertical and horizontal rigidity in empirical analysis. The partial price adjustment after a shock may not be the consequence of the inability to adjust prices *tout court* (vertical rigidity) but instead be the consequence of the inability or unwillingness to adjust them differently in different markets (horizontal rigidity). Fourth, we show empirically for the first time that the magnitude and sign of the exchange rate pass-through depends also on country characteristics, namely the size of the country whose exchange rate varies, distance of exporters from that country, price difference between the destination countries, and the proportion of firms that are unable or unwilling to price discriminate between markets. The theoretical model provides the rationale for the use of these variables in the empirical analysis. Fifth, in empirical studies it may be essential to take the full measure of a firm's ability to price discriminate to limit estimation biases. This point does not only apply to the exchange rate shock but also to the estimation of trade elasticities or cost shocks. Indeed, the pass-through estimated using firm-time fixed effects may underestimate severely the actual pass-through if the share of firms that do not price discriminate between markets is large. Sixth, from a macroeconomic perspective, the fact that some firms do not price-discriminate between markets changes the pattern and magnitude of international monetary policy transmission.

The remainder of the paper is structured as follows. We develop a model in section 2 that exhibits the heterogeneous behavior of firms showcased above. In section 3 we take another look at the data, before estimating the differential effect of French exporters to the dramatic change in the exchange rate in section 4. Section 5 concludes.

## 2 Theoretical background

We sketch a simple two-good three-country model. The three countries are labeled F(rance), E(urozone) and S(witzerland). The first two have the same currency (Euro) while the latter has a different currency (CHF). The extensions to multiple countries and goods is trivial. Our benchmark model structure, discussed in section 2.1, is the traditional Dixit-Stiglitz-Krugman monopolistic competition with an outside good. To this structure we add two elements. First, we introduce destination-specific marginal costs to capture a feature of the data. Second, and more importantly, we introduce a single-price constraint for some firms. The single-price constraint is the key element that gives rise to incomplete or more than complete pass-through and to the pass-around effect. Furthermore, single pricing makes that the magnitude of the pass-through (and of the pass-around) depend on market size and trade costs, two variables so far ignored by the literature. The underlying model structure is purposely simple to highlight the fact that incomplete pass-through may arise also in the absence of flexible markup when firms are unable or unwilling to price discriminate between markets. In section 2.2 we show that the results obtained in the benchmark model are robust to alternative plausible model structures. In that section we embed the single-price constraint first in a model that features a variable elasticity of demand, and, second, in a model that exhibits marginal costs depending on the exchange rate. These two alternative model structures capture two sources of incomplete pass-through very often identified in the literature. Single-pricing in these model alternatives produces qualitatively the same results as in the simple set up we discuss section 2.1.

### 2.1 A simple benchmark model

**Consumers.** The representative consumer has Cobb-Douglas preferences defined over two goods indexed by  $g$ , ( $g = X, Y$ ) with expenditure shares  $\gamma_g > 0$  and  $\sum_g \gamma_g = 1$ . Good  $Y$  is our outside good; it is homogeneous, its technology requires one unit of labor input per unit of output, it is freely traded, and will serve as numéraire. This, combined with incomplete specialization implies that the wage is equal to 1 in every country. Good  $X$  is assumed to be a CES aggregate with elasticity of substitution equal to  $\sigma$ . Let  $p_{ij}$  be the price in  $j$  expressed in the currency of  $j$  of any variety produced in  $i$  and sold in  $j$ . Let  $A_i = P_i^{\sigma-1} \gamma_X I_i$  be the demand shifter for good  $X$  applicable to  $i = F, E, S$ ; where  $I_i$  is national income and  $P_i$  is the local price index all expressed in local currency. To lighten notation we omit the subscript referring to good  $X$  in prices and price indices. This will not induce confusion since  $Y$  is our numéraire. Given preferences and the budget constraint, demand functions take the usual form. For instance, a firm located in  $F$  faces the following demand functions in each market:  $d_{Fj} = p_{Fj}^{1-\sigma} A_j$ , with  $j = F, E, S$ . Analogous demand functions apply to firms in the other countries. Since we focus

on firms in  $F$  and since results for the other countries are analogous we drop the first subscript from prices and other variables.

**Firms and pricing rules.** Firms producing good  $X$  face a fixed production cost  $F$  and a constant marginal cost  $c_i$  specific to the destination. Trade across borders is costly, for any unit of good shipped to  $i$  only a fraction  $\tau_i \in (0, 1)$  arrives at destination. To set a price specific to each market a firm has to pay a fixed cost  $F_t$  (t for pricing-to-market). Some firms will pay  $F_t$  and adopt the pricing-to-market policy while other firms will not pay  $F_t$  and adopt the alternative policy of a single price. The latter are bound to apply the same price to all destinations. The different policy adoptions across firms may be justified by having in mind firm heterogeneity à la Melitz (2003) whereby only the most productive firms generate enough revenues to be able to pay  $F_t$ . We leave this well known mechanism in the background. Let  $e$  be the units of Euro needed to buy one unit of CHF. The firm's profit is

$$\pi = p_F^{1-\sigma} A_F + p_E^{1-\sigma} A_E + e p_S^{1-\sigma} A_S - c_F p_F^{-\sigma} A_F - c_E \frac{p_E^{-\sigma} A_E}{\tau_E} - c_S \frac{p_S^{-\sigma} A_S}{\tau_S} - (F + F_t). \quad (1)$$

with  $F_t = 0$  for firms that opt for single-pricing. Since all the action is on the export prices, the domestic market may be neglected without loss of generality but with great gains in terms of length of mathematical expressions. We then set fictitiously  $A_F = 0$  henceforth.

Pricing-to-market. We use the term pricing-to-market in the sense of Krugman (1987), that is, the ability of the firm to formulate independent profit-maximizing pricing rules in different markets. A firm that pays  $F_t$  maximizes  $\pi$  with respect to  $p_E$  and  $p_S$  obtaining the well known profit-maximizing prices  $p_E = \frac{\sigma}{(\sigma-1)\tau_E} c_E$  and  $p_S = \frac{\sigma}{(\sigma-1)\tau_S e} c_S$  to which correspond the Euro-denominated FOB prices

$$p_E^{FOB} = \frac{\sigma}{(\sigma-1)} c_E, \quad p_S^{FOB} = \frac{\sigma}{(\sigma-1)} c_S. \quad (2)$$

Single-pricing. A firm that does not pay  $F_t$  maximizes profits by choosing a single FOB price. We denote this single Euro-denominated FOB price as  $p_\zeta^{FOB}$ .<sup>5</sup> All other prices depend on this one in the following way:

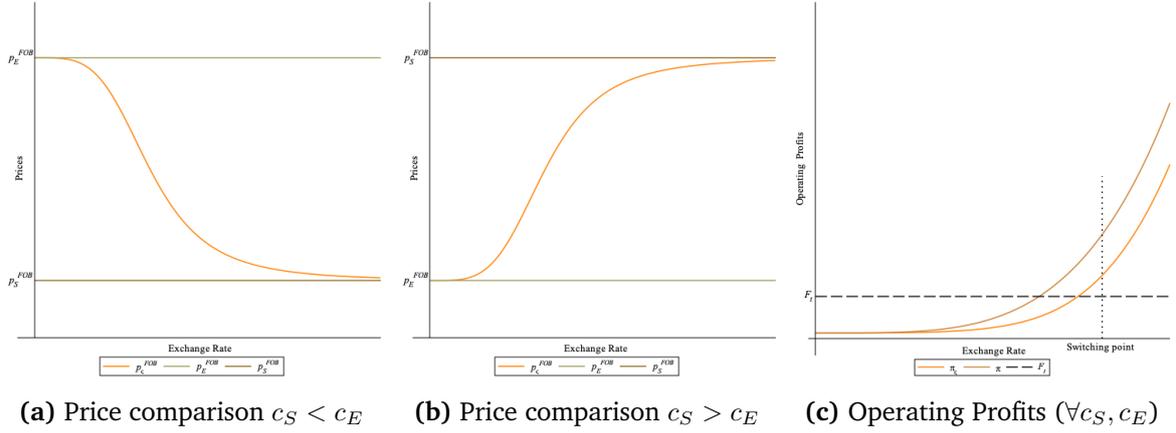

$$p_E = p_\zeta^{FOB} / \tau_E, \quad p_S = p_\zeta^{FOB} / (\tau_S e) \quad (3)$$

The profit of a single-price firm is the same as in expression (1) except that  $F_t$  is set to zero. Maximizing this profit subject to (3) gives

$$p_\zeta^{FOB} = \frac{\sigma}{(\sigma-1)} \frac{A_S c_S \tau_S^{\sigma-1} e^\sigma + A_E c_E \tau_E^{\sigma-1}}{A_S \tau_S^{\sigma-1} e^\sigma + A_E \tau_E^{\sigma-1}}. \quad (4)$$

The single FOB price in equation (4) is between the two distinct FOB prices in equation (2). This

<sup>5</sup>The Free On Board (FOB) price is the price of the traded goods at the border of the exporting country, which does not include international transport costs. Export declarations are valued at FOB prices. It is therefore these prices that we approximate with the unit values of export flows recorded in the customs data we use in our empirical analysis.

**Figure 4: FOB prices and Operating profits**

is intuitive since the single price captures features of both markets. As the exchange rate goes from zero to infinity the single FOB price goes from  $p_E^{FOB}$  to  $p_S^{FOB}$  as revenues from the  $S$  market become more and more important. This convergence towards  $p_S^{FOB}$  implies a price increase or a price decrease depending on which of the two prices is the largest. Panels 4a and 4b of Figure 4 show these convergences.

Comparing profits is also interesting. Operating profits under pricing-to-market are always larger than under single pricing. The reason is that single-price maximization is subject to the binding constraint (3) while pricing-to-market is not. However, for small  $e$  the  $S$  market matters very little and paying  $F_t$  does not give a great push to profits. The firm prefers to adopt a single price in this case. Conversely, for large  $e$ , paying  $F_t$  gives a push to profits larger than  $F_t$  and the firm prefers to adopt the pricing-to-market policy. The switching point between the two pricing rules is represented in Panel 4c of Figure 4 where the vertical distance between operating profits exactly equals  $F_t$ . Having in mind the heterogeneous firm model, the switching point will be different for different firms, which explains the coexistence of different price policies. As  $e$  increases, more and more firms will adopt pricing-to-market. This result will be useful in understanding the dynamics of mean price changes discussed below.

**Pass-through and pass-around.** Let  $\hat{x} \equiv dx/x$  be the percentage change for any variable  $x$ . Pricing-to-market. Using optimal prices in equations (2) we see that the FOB prices are independent of the exchange rate. Therefore, the exchange rate shock leaves them unchanged:

$$\hat{p}_E^{FOB} = 0, \quad \hat{p}_S^{FOB} = 0. \quad (5)$$

As for the pass-through we have  $\hat{p}_S = -\hat{e}$ , which is complete exchange rate pass-through.<sup>6</sup>

Single-pricing. Consider now a firm that does not pay  $F_t$ . Using (4) we obtain the price change

<sup>6</sup>To keep the terminology clear we use the term pass-through as defined in Deardorff (2014); that is, the extent to which an exchange rate change is reflected in the prices of imported goods.

induced by the exchange rate shock  $\hat{e}$ , which is

$$\hat{p}_\zeta^{FOB} = \frac{(c_S - c_E) \sigma e A_S A_E (\tau_E \tau_S)^{\sigma-1} \hat{e}}{(\tau_E^{\sigma-1} c_E A_E + e^\sigma \tau_S^{\sigma-1} c_S A_S) (\tau_E^{\sigma-1} A_E + e^\sigma \tau_S^{\sigma-1} A_S)} \gtrless 0. \quad (6)$$

The FOB price change can be positive, zero, or negative depending on whether  $c_S \gtrless c_E$ . This is also shown in Figure 4 where we see that a depreciation (moving on the right on the abscissa) moves the single FOB price to approach the pricing-to-market FOB price to  $S$ . This means an increase or a decrease of the single FOB price depending on whether the marginal cost  $c_S$  is larger or smaller than  $c_E$ . The pass-through can be incomplete, complete, or more than complete depending on the same conditions. The important thing here is that the exchange rate shock brings about the same price change to all destinations, not only to market  $S$ . This is the pass-around effect and is due to single-pricing. An important implication of this finding in relation to the empirical literature is that single-pricing may be one of the causes of the incomplete pass-through. This possibility has so far remained unexplored in the literature, which may have led to overestimating the importance of other factors.

**Sensitivity to market size and trade costs.** Under pricing-to-market, the FOB price response to the exchange rate shock is zero and therefore it is independent of the market size and trade costs. Conversely, the single-price response in expression (6) is sensitive to the size of demand shifter and to trade costs. Proximity to market  $S$  (i.e., an increase in  $\tau_S$  relative to  $\tau_E$ ) has ambiguous effects on  $\hat{p}_\zeta^{FOB}$  shown in the following inequalities:

$$\frac{\partial \hat{p}_\zeta^{FOB}}{\partial \tau_S} > 0 \Leftrightarrow \left\{ \begin{array}{l} c_S > c_E \quad \wedge \quad \left( \frac{\tau_E}{\tau_S} \right)^{2(\sigma-1)} \left( \frac{A_E}{A_S} \right)^2 \frac{c_E}{c_S} e^{-2\sigma} > 1 \\ \text{or} \\ c_S < c_E \quad \wedge \quad \left( \frac{\tau_E}{\tau_S} \right)^{2(\sigma-1)} \left( \frac{A_E}{A_S} \right)^2 \frac{c_E}{c_S} e^{-2\sigma} < 1 \end{array} \right. \quad (7)$$

with analogous conditions holding for  $\frac{\partial \hat{p}_\zeta^{FOB}}{\partial \tau_S} < 0$ .

In our empirical analysis, based on French custom declarations, we find that proximity to Switzerland has a positive effect on the pass-around effect. It is interesting to check what this empirical finding implies for the parameters of our models. To this purpose we may perform a crude numerical example using plausible parameter values. Using World Bank data we may set  $A_S$  to be 5.8% of  $A_E$ , our own estimations suggest to set  $c_S$  to be 30% larger than  $c_E$ , the pre-shock level of the exchange rate is observed at 0.83 (Figure 1), as per the elasticity we take a customary  $\sigma = 4$ . With this numbers, the second set of inequalities in the first row of equation (7) becomes  $\left( \frac{\tau_E}{\tau_S} \right)^6 \times 1089 > 1$ . To satisfy this inequality and therefore have  $\frac{\partial \hat{p}_\zeta^{FOB}}{\partial \tau_S} > 0$  the ratio  $\tau_E/\tau_S$  must be not too small. The ratio  $\tau_E/\tau_S$  is almost certainly smaller than one since, for French exporters, business destinations in Switzerland are — on average — closer than those in the Eurozone (remember that  $\tau_i \in (0, 1)$  is the fraction of the good evaporated in transit). For simplicity, we may assume overall trade costs to be proportional to distances  $d_j$ , so that

$\tau_j = 1/(1 + d_j)$ . With the simulation values above, the condition  $\frac{\partial \widehat{p}_\zeta^{FOB}}{\partial \tau_S} > 0$  is met when the distance to the Eurozone is not larger than 5.3 times the distance to Switzerland. The road distance between Paris and Athens (which is the Eurozone capital furthest away from France) is only 4.8 times the distance between Paris and Zurich. Furthermore, Athens is not the center of the Eurozone market relative to France. If we take the center of gravity of the Eurozone relevant for France to be an average between Berlin, Madrid and Rome we have a road distance which is only twice the distance to Zurich. With these numbers, the theoretical prediction is consistent with the empirical finding that the pass-around effect is positive and that proximity to Switzerland amplifies the exchange rate pass-around. Obviously, the numerical example is sensitive to the value of  $\sigma$ , but with the Eurozone at twice the distance to Switzerland, it would take an unlikely  $\sigma > 14$  for the model prediction to be inconsistent with the empirical finding. The effect of the market size on  $\widehat{p}_\zeta^{FOB}$  has a qualitatively similar effect to the effect of trade costs to  $S$ . Aside from the quantitative prediction, single-pricing makes the price response sensitive to trade costs and market size while pricing-to-market does not.

**Dynamics of mean price changes.** Our empirical analysis will describe the average change of exporters' prices over several months. We therefore need to track the mean price change theoretically. In doing so we take into account the possibility that some firms decide to change their pricing policy. We have seen above that the switching point is different for different firms. Thus, after the exchange rate depreciation some firms will switch to pricing-to-market. These firms will switch from  $p_\zeta^{FOB}$  to  $p_E^{FOB}$  and  $p_S^{FOB}$ . Presumably, the switch takes place some time after the shock as firms have to realize the switch is profitable and have to reorganize their pricing policy. Let  $\lambda_z$  be the percentage of firms that have switched from a single-price to a pricing-to-market strategy between the day of the shock and  $z$  days after the shock. Then, the mean price change on market  $J = E, S$  observed between the day of the shock and  $z$ , denoted  $\mu_z^J$ , is

$$\mu_z^E = (1 - \lambda_z)\widehat{p}_\zeta^{FOB} + \lambda_z(p_E^{FOB} - p_\zeta^{FOB}), \quad (8)$$

$$\mu_z^S = (1 - \lambda_z)\widehat{p}_\zeta^{FOB} + \lambda_z(p_S^{FOB} - p_\zeta^{FOB}). \quad (9)$$

As shown in Figure 4,  $p_\zeta^{FOB}$  lies between  $p_E^{FOB}$  and  $p_S^{FOB}$ . Therefore, the second terms of equations (8) and (9) have opposite sign. Since the optimal price changes of pricing-to-market firms are zero,  $\mu_z^E$  and  $\mu_z^S$  measure the average ERPA and ERPT, respectively. If  $p_S^{FOB} > p_E^{FOB}$  we expect an attenuation of the ERPA and an increase of the ERPT as we measure the price change over longer time intervals (larger  $z$ ). Vice-versa if  $p_S^{FOB} < p_E^{FOB}$ . This result will be useful in the interpretation of Figure 6.

## 2.2 Model extensions

In addition to highlighting the pass-around effect, one of the contributions of the theoretical model above is to suggest an original mechanism generating the incomplete pass-through. This section discusses alternative arguments that also give rise to incomplete pass-through and which

are now standard in the literature. These arguments are insufficient to explain the pass-around effect we have identified in the data. We want to show, however, that they are compatible with the mechanism through which single-pricing generates a pass-around effect.

**Variable elasticity of demand.** In models with a variable elasticity of demand the exchange rate pass-through is incomplete and its magnitude depends on the productivity of the firm. These two results arise from the first order conditions for profit maximization,  $p_S^v = \frac{w}{\phi e \tau} \frac{\nu(x)}{\nu(x)-1}$ , where  $x$  is firm output sold to  $S$  and  $\nu(x) \equiv -\frac{dx}{dp} \frac{p}{x} > 1$  is the price elasticity of demand. The firm chooses the position on the demand curve and would obviously not choose a point in the demand curve where the elasticity is less than one. This explains why  $\nu(x) > 1$ . We have used the superscript  $v$  to refer to the variable markup model. The first order condition defines the pricing rule only implicitly because  $x$  is a function of  $p$ . The FOB price is  $p_S^{FOB,v} = e p_S^v$  and its percentage change induced by a depreciation of the Euro is

$$\widehat{p}_S^{FOB,v} = e \frac{\partial \nu(x) / \partial e}{\nu(x)(\nu(x) - 1)} \widehat{e} = -\frac{\eta(x)}{\nu(x) - 1} \widehat{e}$$

where  $\eta(x) \equiv -\frac{\partial \nu(x)}{\partial e} \frac{e}{\nu(x)} = \frac{\partial \nu(x)}{\partial p} \frac{p}{\nu(x)}$ . The key assumption of this class of models is  $\eta(x) < 0$  so that the FOB price increases after the exchange rate depreciation. Two seminal papers that incorporate this assumption (in more elaborate settings) are Melitz and Ottaviano (2008) and Zhelobodko et al. (2012). Since  $\widehat{p}_S^v = (\widehat{p}_S^{FOB,v} - 1) \widehat{e}$ , it follows that the pass-through is less than complete. The economic mechanism is that the exchange rate shock pushes the firm to reduce the consumer price. This induces an increase in consumption ( $x$ ) and thereby a reduction in  $\nu(x)$  thus giving rise to a positive feedback on the price. As a result, the consumer price declines, but less than proportionally with respect to the exchange rate. If the elasticity of demand were constant, then  $\eta = 0$ ,  $\widehat{p}_S^{FOB,v} = 0$ , and  $\widehat{p}_S^v = -\widehat{e}$  with perfect pass-through. Without a single-price mechanism the pass-around effect does not arise from this class of models. Inserting a single-price constraint in this class of models gives rise to results qualitatively identical to those shown in the previous section. This can be seen by sketching a simple model with linear (inverse) demand given by  $p_i^v = (a - bq_i)A_i$  for  $i = E, S$ . Then the optimal prices are

$$\begin{aligned} p_E^{FOB,v} &= \frac{aA_E\tau_E + c_E}{2} & p_S^{FOB,v} &= \frac{eaA_S\tau_S + c_S}{2} \\ p_\zeta^{FOB,v} &= \frac{A_EA_Sae\tau_E\tau_S(\tau_E + \tau_S) + c_E\tau_S^2c_EeA_S + c_SA_E\tau_E^2}{2(\tau_S^2c_EeA_S + A_E\tau_E^2)} \end{aligned}$$

with price changes

$$\begin{aligned} \widehat{p}_E^{FOB,v} &= 0, & \widehat{p}_S^{FOB,v} &= \frac{eaA_S\tau_S}{eaA_S\tau_S + c_S} \widehat{e} \in (0, \widehat{e}) \\ \widehat{p}_\zeta^{FOB,v} &\geq 0 \Leftrightarrow A_E \geq \frac{\tau_S(c_S - c_E)}{a\tau_E(\tau_S + \tau_E)} \end{aligned} \quad (10)$$

where inequality (10) can be verified by simple calculus. These results are qualitatively similar to those of the simple model of constant markup presented in the previous section, except that

the ERPT for pricing-to-market firms is now incomplete.

**Exchange rate in the marginal cost.** This class of models assumes that part of the marginal cost of production is paid in the destination currency. As a result, the exchange rate variation influences the FOB price and the pass-through is incomplete. The first model of this family is in Corsetti and Dedola (2005). To sketch this mechanism and keep the notation as simple as possible, let the marginal cost  $c_S$  of the previous section be a function of the exchange rate, say  $c_S = e c_S$  with  $c_S > 0$ . Then, optimal FOB prices would be:

$$\begin{aligned} p_E^{FOB,mc} &= \frac{\sigma c_E}{\sigma - 1}, & p_S^{FOB,mc} &= \frac{e c_S \sigma}{\sigma - 1}, \\ p_\varsigma^{FOB,mc} &= \frac{\sigma}{\sigma - 1} \frac{A_S c_S \tau_S^{\sigma-1} e^{1+\sigma} + A_E c_E \tau_E^{\sigma-1}}{A_S \tau_S^{\sigma-1} e^\sigma + A_E \tau_E^{\sigma-1}}. \end{aligned}$$

where we have used the superscript  $^{mc}$  to indicate that this is the model with the exchange rate in the marginal cost. The percentage price changes are

$$\begin{aligned} \hat{p}_E^{FOB,mc} &= 0, & \hat{p}_S^{FOB,mc} &= \hat{e}, \\ \hat{p}_\varsigma^{FOB,mc} &> 0 & \left\{ \begin{array}{l} \frac{(1+\sigma)c_S}{\sigma c_E} > 1 \\ \text{or} \\ \frac{(1+\sigma)c_S}{\sigma c_E} < 1 \quad \wedge \quad \left(\frac{\tau_E}{\tau_S}\right)^{(\sigma-1)} \frac{A_E}{A_S} \frac{\sigma c_E - (1+\sigma)c_S}{e^\sigma c_S} < 1 \end{array} \right. \end{aligned} \quad (11)$$

where the inequalities in (11) can be verified by simple calculus. In this simple example the pass-through for pricing-to-market firms is zero because the marginal cost is proportional to the exchange rate. Of course, the magnitude of the pass-through may be larger than zero if we assume a nonlinear relationship between the marginal cost and the exchange rate or, more plausibly, if only a fraction of the marginal cost is paid in foreign currency. For single-price firms the pass-around effect may be positive or negative and its magnitude depends on parameter values. Again, the exchange rate pass-around effect is the result of the single-price constraint.

### 3 Data and descriptive statistics

We now turn to the empirical analysis which exploits data on French customs declarations. These provide the values and quantities exported each month, by each French exporter, for each product (8-digit of the combined classification), and each destination country. For flows to non-EU members we also know the invoicing currency. If, in a given month, a firm that exports a given good to a given destination uses different currencies, the transactions using each currency will be recorded as distinct flows. We use unit values (i.e. export value/quantity ratios) as a proxy for FOB prices. We limit our analysis to exports to the Eurozone countries and Switzerland, registered each month between January 2014 and December 2015.

For the econometric analysis, we consider each firm-product pair as an independent individual.

From now on, the terms “firms” and “exporters” will refer to a firm-product pair. Unit values are imperfect proxies for prices and we need to trim the data to remove the most obvious misrepresentations of prices. The 8-digit classification is very detailed, but it is always possible that a firm exports different varieties of the same product with different quality levels. In order to limit the risk that our results are driven by composition effects, we exclude firm-product pairs that have too much variability in unit values, in space and/or time. We eliminate firms that have at least 10% of monthly flows with prices 10 times higher or 10 times lower than the average. We also exclude firm-product pairs whose ratio between the largest and smallest unit value is greater than thirty. Lastly, we exclude products entirely when the max/min ratio exceeding thirty is present for more than half of their exporting firms. In the customs declarations, the quantities declared are rounded to the nearest kilo. For products (especially those with a high price per kilo) for which the average shipment has a very low weight, this rounding can result in a large volatility of unit values. Therefore, we eliminate from the sample all products with an average weight of monthly shipments below 10 kilograms. As we are interested in the evolution of prices before and after the Swiss Franc exchange rate shock, the group of exporters to Switzerland is limited to firms that export to Switzerland in both 2014 and 2015.

After this trimming, our main database contains more than 7 million observations, with 24 months, 19 countries (all Eurozone,<sup>7</sup> minus France, plus Switzerland), 57,404 firms, 8,067 products and 502,684 firm-product pairs. Among the latter, 42,762 firm-products pairs export to Switzerland both in 2014 and 2015. The empirical analysis below focuses on firms that invoice their exports to Switzerland in Euro. Results for those invoicing in Swiss francs are shown in the appendix. This reduces the treated group to 37,281 firm-product pairs, accounting for 7.5% of the firm-product pairs and 16.57% of the observations.

**Invoicing currency.** As shown in Figure 3 above, the prices of exports invoiced in CHF (once converted into Euros) and in Euros react very differently to the appreciation of the franc. This confirms the necessity of distinguishing between flows according to the invoicing currency. We therefore allocate exporters to Switzerland into three groups according to their invoicing currency. We consider a firm-product pair as invoicing in Euros if at least 99% of the total value exported to Switzerland both in 2014 and 2015 is invoiced in this currency. Similarly, a firm-product pair is defined as invoicing in Swiss Franc if the invoices in CHF represent more than 99% of the total value exported to Switzerland in both years. The remaining group (called “Mixed”) includes therefore firms that use both currencies simultaneously in significant proportions, and also those who use a vehicle currency. Table 1 shows how the choices in terms of invoicing currency are distributed among exporters to Switzerland. The population of firms is distributed between bins combining the percentages of exports to Switzerland invoiced in Euros and the percentage invoiced in CHF. The top-left corner indicates that 89.65% of the exporters invoice at least 99% of their exports in Euros and — of course — less than 1% in CHF. Conversely, in the bottom-right corner, we have firms that form the group of Swiss Franc exporters. They account for 6.9% of

---

<sup>7</sup>In 2014 and 2015, there were only 19 countries in the Eurozone. Croatia joined in 2023.

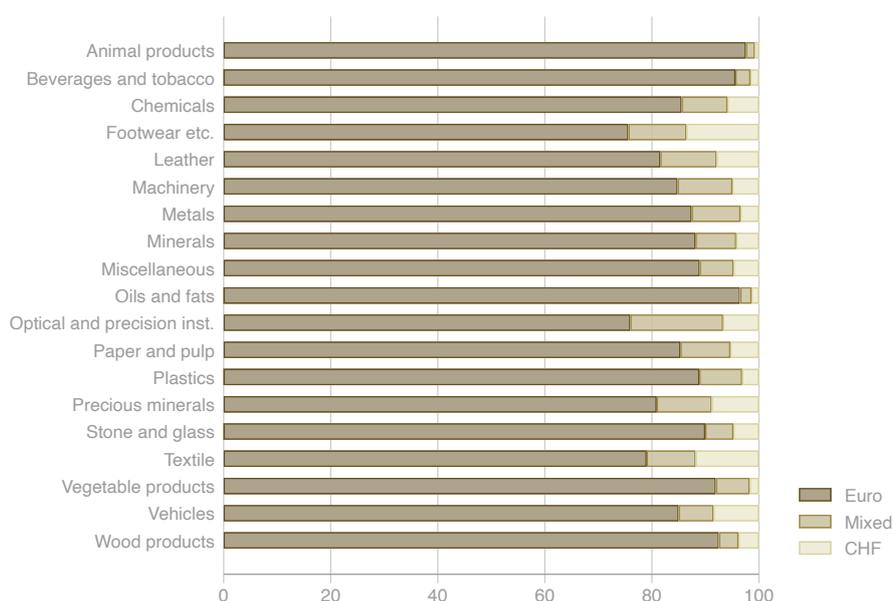

**Table 1:** % of exporters to Switzerland by bins of shares of Euro and CHF invoices

		Share of exports invoiced in CHF							
		< 1%	1-10%	10-25%	25-50%	50-75%	75-90%	90-99%	> 99%
Share of exports invoiced in Euro	> 99%	89.653							
	90-99%	0.077	0.371						
	75-90%	0.04	0	0.377					
	50-75%	0.04	0	0.006	0.604				
	25-50%	0.04	0	0	0.004	0.451			
	10-25%	0.04	0	0	0	0.01	0.336		
	1-10%	0.024	0	0	0	0.002	0.002	0.485	
	< 1%	0.509	0.004	0.004	0.004	0.008	0	0.004	6.903

all exporters to Switzerland. All other cells form the group of *Mixed* firms. All together these firms account for only 3.4% of exporters to Switzerland. Among the latter, only 0.5% use almost exclusively a vehicle currency (see bottom-left corner).

This strong dominance of the Euro in trade with Switzerland is confirmed by Figure 5, which shows its high share across the universe of tradable products. Hence, the focus on Euro-invoicing firms in the main body of the paper.

**Figure 5:** Share Euro, CHF and Mixed invoicing exporters, by product category (2014)

## 4 Econometric analysis

We conduct two difference-in-differences analyses. The first one is a two-way fixed effects study comparable to the standard specification to estimate the exchange rate pass-through at the firm level (see e.g. Berman et al., 2012). In order to assess the impact of the exchange rate shock on

exporters' prices, we estimate the change in export prices on the Swiss market, relative to the one on other European markets, for the same firm-product and date. Formally, this first model is:

$$\ln Price_{i,k,c,t} = \alpha ERPT_{c,t} + \Theta_{i,k,c} + \Theta_{i,k,t} + \varepsilon_{i,k,c,t}. \quad (12)$$

In equation (12), subscripts  $i$ ,  $k$ ,  $c$ , and  $t$  denote a firm, a product, a destination country and date (month-year), respectively.  $Price_{i,k,c,t}$  is the unit value of the monthly exports of firm-product pair  $i, k$  in the European country  $c$  at date  $t$ . The treatment dummy,  $ERPT_{c,t}$ , takes the value of one for exports to Switzerland on months after the CHF appreciation (i.e. from February to December 2015).  $\varepsilon_{i,k,c,t}$  is an error term. Fixed effects  $\Theta_{i,k,c}$  and  $\Theta_{i,k,t}$  control for all firm-product-destination and firm-product-time characteristics, respectively. By adding firm-products-time fixed effect, this specification eliminates all exogenous shocks that may have affected firms and modified their prices in all markets. The estimated  $\alpha$  tells us to what extent firms have increased their prices in the Swiss market more than in other markets. For pricing-to-market firms, our theoretical framework predicts complete or incomplete (but not zero) exchange rate pass-through, with  $\alpha = 0$  (i.e. complete ERPT) in the benchmark theoretical model, and  $0 < \alpha \leq \hat{\varepsilon}$  in any of the model extensions. For single-price firms, we unambiguously expect  $\alpha = 0$ . But in this case, it does not mean that these exporters do not change their prices in the Swiss market; they do. This is because they are expected to change their prices simultaneously – and to the same extent – in all their destination markets, so that these price changes will be absorbed by the firm's time fixed effects.

The second specification estimates the magnitude of the exchange rate pass-around effect described in our model. Here, the empirical strategy is to compare the evolution of prices in the Eurozone of firms that export to Switzerland in 2014 and 2015 to the one of firms that do not. We thus estimate the second model as:

$$\ln Price_{i,k,c,t} = \beta ERPA_{i,k,t} + \Theta_{i,k,c} + \Theta_{k,c,t} + \varrho_{i,k,c,t}, \quad (13)$$

where  $\varrho_{i,k,c,t}$  is the error term. The treatment dummy,  $ERPA_{i,k,t}$ , takes the value of one from February 2015 onward for firms that export to Switzerland in both 2014 and 2015. The specification includes firm-product-destination fixed effects,  $\Theta_{i,k,c}$ , along with product-country-time fixed effects,  $\Theta_{k,c,t}$ . A  $\beta \geq 0$  is the ERPA<sup>8</sup> and is consistent with the single-price mechanism of the model, while an absence of the ERPA ( $\beta = 0$ ) is not.

#### 4.1 Pass-through and pass-around

Table 2 reports estimates for the two models obtained with different samples of firms, products and destinations. Odd rows show the pass-through estimates (model 1), while even rows show the pass-around (model 2).<sup>9</sup>

<sup>8</sup>More precisely, we predict  $\beta > 0$  if  $c_S > c_E$ , i.e., if, as is clearly the case in our data, the price of exports to Switzerland is higher on average than that of flows to the Eurozone.

<sup>9</sup>Appendix A shows the results with a treated group made of exporters invoicing in CHF, and appendix B shows robustness checks using alternative difference-in-differences settings and estimators.

**Table 2:** Exchange rate pass-through (ERPT) and pass-around (ERPA) for firms invoicing in Euro

	<i>Currency</i>	<i>Importers</i>	<i>Homog. products</i>	<i>Destinations</i>	<i>Treatment period</i>	<i>Variable</i>	<i>Coefficient</i>	<i>Standard err.</i>	<i>Sample size</i>
(1)	Euro	Yes	Yes	EZ	Feb-Apr	ERPT <sub>c,t</sub>	0.016a	(0.004)	3,997,203
(2)	Euro	Yes	Yes	EZ	Feb-Apr	ERPA <sub>i,k,t</sub>	0.005b	(0.002)	3,997,203
(3)	Euro	No	Yes	EZ	Feb-Apr	ERPT <sub>c,t</sub>	0.015a	(0.006)	2,201,310
(4)	Euro	No	Yes	EZ	Feb-Apr	ERPA <sub>i,k,t</sub>	0.009a	(0.003)	2,201,310
(5)	Euro	No	No	EZ	Feb-Apr	ERPT <sub>c,t</sub>	0.015b	(0.007)	1,917,676
(6)	Euro	No	No	EZ	Feb-Apr	ERPA <sub>i,k,t</sub>	0.008a	(0.003)	1,917,676
(7)	Euro	No	No	EZ	Feb-Jun	ERPT <sub>c,t</sub>	0.016a	(0.006)	2,151,839
(8)	Euro	No	No	EZ	Feb-Jun	ERPA <sub>i,k,t</sub>	0.005c	(0.003)	2,151,839
(9)	Euro	No	No	EZ	Feb-Dec	ERPT <sub>c,t</sub>	0.021a	(0.005)	2,876,291
(10)	Euro	No	No	EZ	Feb-Dec	ERPA <sub>i,k,t</sub>	0.002	(0.003)	2,876,291

*Notes:* Significance levels: c:  $p < 0.1$ , b:  $p < 0.05$ , a :  $p < 0.01$ . Pre-treatment period: Jan.-Dec. 2014. Standard errors are clustered by destination-date and firm-product. The dependent variable is the log of export prices denominated in Euros. Lines 3-10 exclude all firms that import from Switzerland in 2015. Lines 5-10 exclude homogeneous products (cf. Rauch's liberal product classification).

Lines (1) and (2) use the whole sample of firms that either do not export to Switzerland and those who export to Switzerland invoicing in Euros. The treatment period is limited to 3 months: February-April 2015. In lines (3) and (4) we exclude firms that import from Switzerland in 2015. This shuts down the channel between the exchange rate shock and the export price through a change in the inputs prices. Lines (5) and (6) further exclude homogeneous products (cf. Rauch, 1999) and rows (7) to (10) expand the treatment window to February-June and February-December, respectively.

Across specifications for the first model, i.e. those reported in odd-numbered rows, the estimates reveal that French exporters reacted to the exchange rate shock by significantly increasing the price they set on the Swiss market (relatively to their price on Eurozone destinations). The exchange rate pass-through is therefore incomplete and the magnitude is comparable to that reported in the related literature. Using the same French customs data, Berman et al. (2012) report an exchange rate pass-through of 92% (i.e. the average French exporter increases its export price by 0.08% following a 1% real exchange rate depreciation, with the remainder  $((1 - 0.08))$  passed on to the foreign consumer).<sup>10</sup> Fontagné et al. (2018), who also use the same data source, find an even larger exchange rate pass-through of about 97%. Our estimates suggest a slightly smaller pass-through (i.e. a larger coefficient  $\alpha$ ), but clearly in the same order of magnitude. After the CHF appreciation, French exporters increased the FOB price charged on the Swiss market by 1.6 to 2.1% (i.e.  $(1 - e^{0.016})$  and  $(1 - e^{0.021})$ , see columns 7 and 9). After a short period of overreaction in January 2015, the appreciation of the Swiss Franc stabilized at around 14% during the first half of 2015 (see Figure 1). All together, this suggests that the price

<sup>10</sup>Berman et al. (2012) study a longer time horizon with a continuum of exchange rate changes.

**Figure 6:** Exchange rate pass-through and pass-around: Euro invoices

response to a 1% CHF exchange rate shock lies between 0.12 and 0.15%, i.e., a pass-through between 88.5 and 84.8%.

More interestingly, the estimates reported in the even-numbered rows — the second model — confirm the presence of a significant pass-around effect. Compared to French exporters who do not export to Switzerland, those who were directly exposed to the exchange rate shock because of their presence on the Swiss market increased their prices to *all* markets in the Eurozone. On average, during the first quarter following the Swiss Franc shock, exporters to Switzerland have increased their prices to the Eurozone by between 0.5 and 0.9% ( $1 - e^{0.05}$  and  $1 - e^{0.09}$ , cf. lines 2 and 6). This initial pass-around is very significant and fades away over the course of the year. The evolution is clearly visible in Figure 6 which shows the dynamics of the pass-through and pass-around over the course of 2015.<sup>11</sup> The figure reports the estimates of our models 1 and 2 for a series of treatment periods expanded progressively from one to twelve months.

The pass-around effect revealed in Table 2 and Figure 6 is consistent with the theoretical predictions of our baseline model combined with any of the model extensions. The empirical results, through the lenses of our model, imply  $p_S^{FOB} > p_E^{FOB}$  (see section 4.3 below for further discussion). In this case, an incomplete ERPT and a positive ERPA are expected, which is corroborated in Figure 6. Furthermore, from equations (8) and (9) we expect an increasing ERPT and a declining ERPA over time. The following sections push the analysis further, by testing more specific theoretical predictions.

<sup>11</sup>The sample is similar to the one used for regressions shown in lines (9)-(10) of Table 2. It excludes firms importing from Switzerland and homogeneous products.

## 4.2 Pass-through and pass-around for single-price and pricing-to-market firms

Our model categorizes firms into two distinct types: Pricing-to-market firms and single-price firms. The pass-around effect is specific to single-price firms only. For those firms, we also expect a pass-through (positive or negative, depending on the difference between  $p_S^{FOB}$  and  $p_E^{FOB}$ ). By contrast, pricing-to-market firms should not show any ERPA ( $\beta = 0$ ), and specification (12) should reveal an incomplete EPRT ( $\alpha > 0$ ). The estimates shown in the previous section only reflect the average impact of the exchange rate shock on these two types of firms, and depend strongly on the proportion of each group in the population at any given time. Ideally, we would like to assess the impact on each group separately.

The distinction between single-price and pricing-to-market firms defined theoretically is, of course, not directly observable in the data. We therefore exploit the variance of prices at the firm level to identify those that more likely set different prices on different markets. However, it is necessary to distinguish between variance in time and in space in order to extract price differences between destinations from temporal fluctuations. To do so, we rely on an entropy index of inequality. Entropy indices measure the concentration of statistical distributions and, as such, they can be applied to a variety of situations, as noted by Brülhart and Traeger (2005). These indices have the double advantage of being simple and exactly decomposable into between and within sub-indices. Precisely, the overall dispersion of prices charged by a given firm in different markets over a given number of time periods can be decomposed into the sum of a within- and a between-country dispersion. For our purposes we retain the simplest entropy measure, the Theil index, defined as follows:

$$Theil_i = \frac{1}{N_i} \sum \frac{p_{idt}}{\bar{p}_i} \log \frac{p_{idt}}{\bar{p}_i},$$

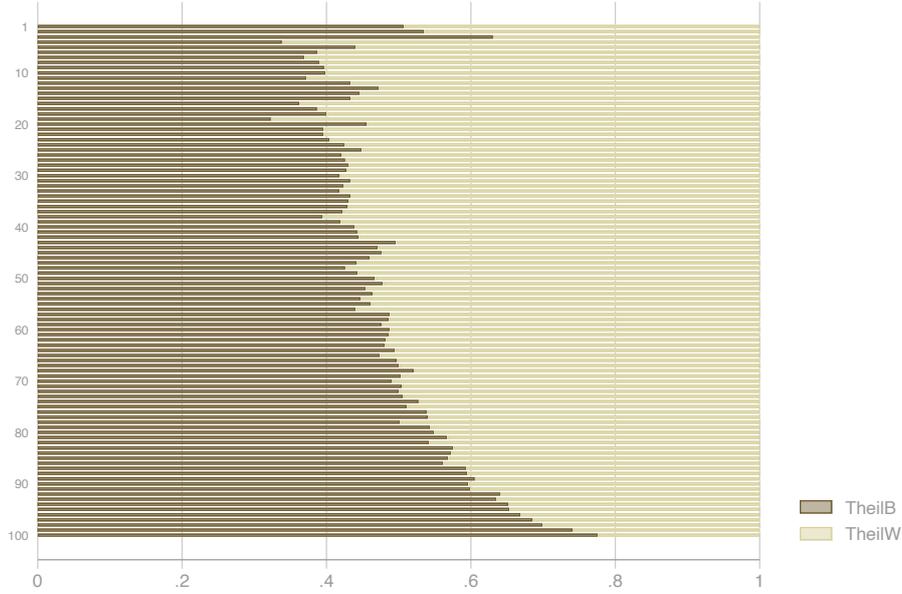

where  $p_{idt}$  is the price charged by firm  $i$  on market  $d$  at date  $t$ ,  $N_i$  is the number of non-zero export flows for firm  $i$  and  $\bar{p}_i$  is the overall average of  $i$ 's prices. The between index,  $TheilB_i$ , captures the price heterogeneity across markets for firm  $i$ . The within index,  $TheilW_i$ , measures the average price heterogeneity within each destination market. It is a weighted average of price heterogeneity within each market (i.e., across time) served by  $i$ . Obviously,  $Theil_i = TheilW_i + TheilB_i$ . The within component of the Theil index is given by:

$$TheilW_i = \sum_d \left( \frac{N_{id}}{N_i} \right) \left( \frac{\bar{p}_{id}}{\bar{p}_i} \right) Theil_{id},$$

where,  $Theil_{id}$  is the Theil index of prices of firm  $i$  in market  $d$ ,  $N_{id}$  is the number of non-zero export flows to destination  $d$ , declared by firm  $i$ , and  $\bar{p}_{id}$  is the average of the prices charged by firm  $i$  on market  $d$ .<sup>12</sup>

Figure 7 shows the decomposition of the 2014 export price variance measured by the Theil index

<sup>12</sup>In their analysis of exporter prices heterogeneity, Fontaine et al. (2020) adopt an alternative approach, based on a heuristic measure of price variance and decomposition. They decompose the total variance of prices,  $VarT_i$ , in a

**Figure 7:** Decomposition of the Theil index - Medians by percentiles of firms' exports to Eurozone+CH

by percentiles of firm size, measured by their total exports to the Eurozone and Switzerland. A few key features emerge. First, the price variance of French exporters, over the year 2014 and in the European neighborhood, is shared almost equally between the two margins. On average the between component represents 54% of the total Theil index.<sup>13</sup> Leaving aside the very small firms — which have very sporadic export flows with sometimes very erratic prices — we also observe a fairly clear relationship between firm size and the importance of the between dimension in the total variance of export prices. This supports the hypothesis that pricing-to-market behavior is more easily accessible to large firms, who are able to pay a fixed cost.

In Table 3 we interact the *ERPT* and *ERPA* treatment variables with dummies indicating whether the treated firms has a low or high *TheilB*. In lines 1 and 2, we divide the sample between firms above or below the median *TheilB*. In lines 3–10, we more strictly separate out the firms most likely to pricing-to-market by retaining those with a *TheilB* above the 75th percentile. As in Table 2, we expand the treatment window from three months (lines 1–4, 7 and 8) to 5 months (lines 5, 6, 9 and 10), and restrict the sample of destinations to Switzerland and its bordering countries

between-country component ( $VarB_i$ ) and a within-country one ( $VarW_i$ ), such that:

$$\begin{aligned}
 VarT_i &= \frac{\sum_{d,t} (p_{idt} - \bar{p}_i)^2}{N_i - 1} \\
 &= \underbrace{\sum_d \left[ \frac{N_{id} - 1}{N_i - 1} \right] \left[ \frac{\sum_t (p_{idt} - \bar{p}_{id})^2}{N_{id} - 1} \right]}_{VarW_i} + \underbrace{\sum_d \left[ \frac{N_{id}}{N_i - 1} \right] [\bar{p}_{id} - \bar{\bar{p}}_i]^2}_{VarB_i}.
 \end{aligned}$$

In our sample, the correlation between  $Theil_i$  and  $VarT_i$  is above 95%, so as the one between  $TheilB_i$  and  $VarB_i$ . The advantage of the Theil index is its theoretically exact decomposition.

<sup>13</sup>Note that the share of the between dimension is significantly higher for firms that export to Switzerland (62%).

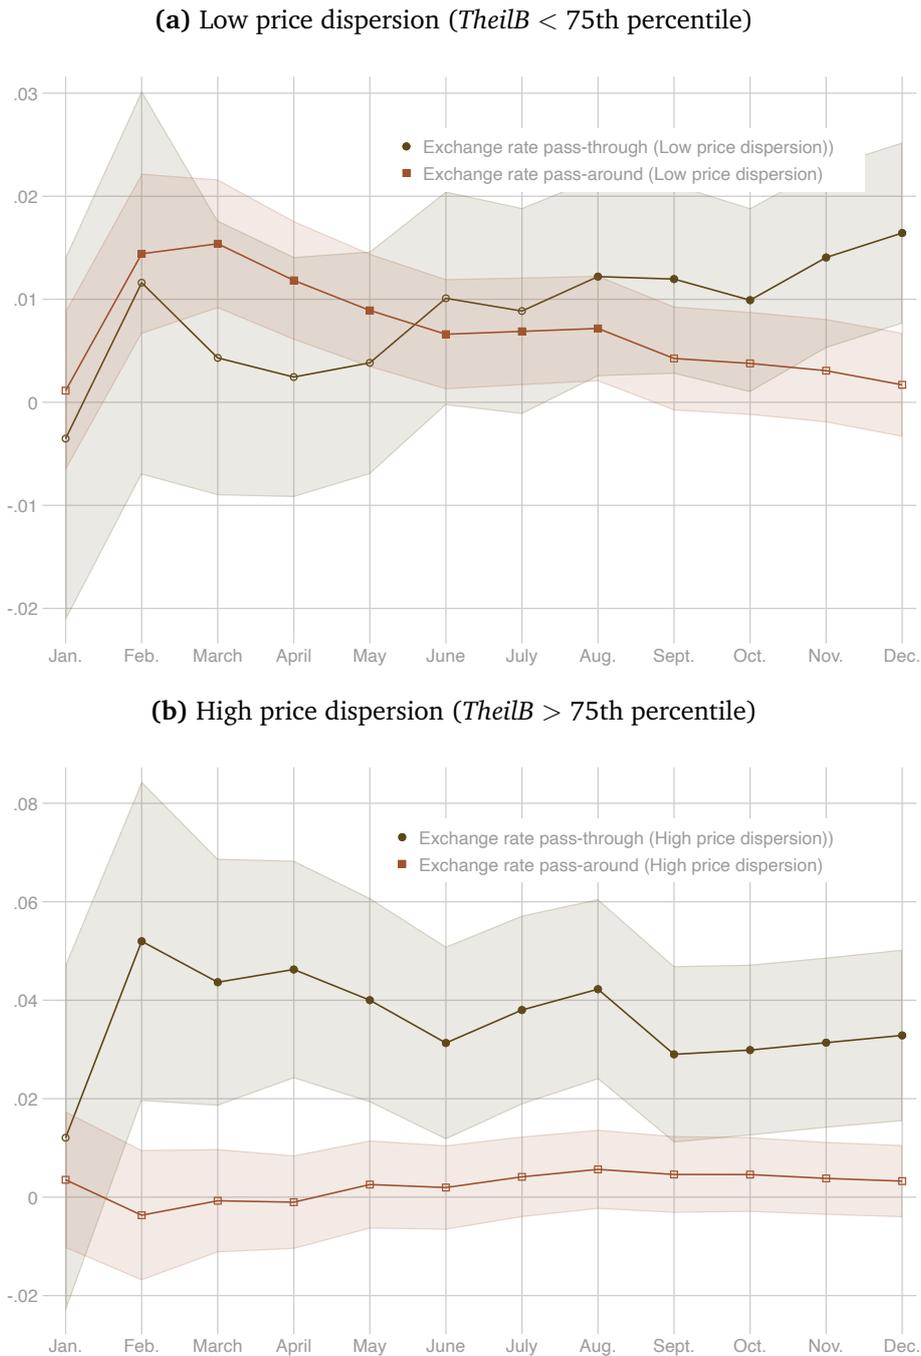

**Table 3:** Firm-level price heterogeneity, exchange rate pass-through (ERPT) and pass-around (ERPA)

	<i>Currency</i>	<i>Destinations</i>	<i>Treatment period</i>	<i>Variable</i>	<i>Coefficient</i>	<i>Standard err.</i>	<i>Sample size</i>

in lines 7–10.

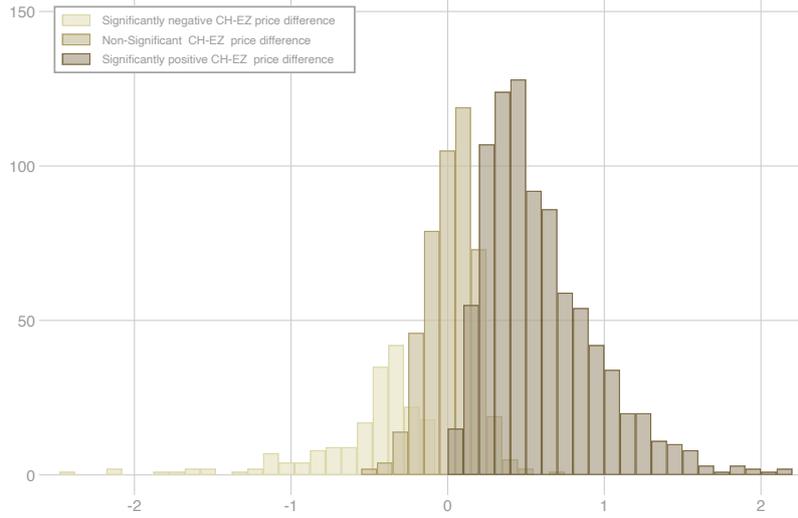

We observe a clear difference in the behavior of firms depending on whether they have a large or low *TheilB*. When the split is at the 75th percentile, the difference between pass-through and pass-around in each group of firms is striking, and corroborates our theoretical prediction. In all cases, the interaction terms show that firms with low *TheilB* did not increase their prices significantly in the Swiss market relative to the ones in other markets ( $\alpha = 0$ ) (cf. odd-numbered lines). Yet, this is clearly not the consequence of an absence of a price reaction. On the contrary, we observe for these firms a significant pass-around effect, as the even-numbered lines tell. This is exactly the behavior expected from single-price firms. Inversely, firms with a *TheilB* above the 75th percentile exhibit a very small and insignificant  $\beta$  coefficient, indicating an absence of the pass-around effect, while their  $\alpha$  is significantly positive and relatively large in magnitude. The absence of a pass-around is the theoretical expectation for pricing-to-market firms. But for these firms, the incomplete pass-through we observe ( $\alpha$  positive but small) is not a prediction of our simple model with constant markup and marginal cost. Rather, this result supports the model

**Figure 8:** Exchange rate pass-through and pass-around by price dispersion

extensions proposed in section 2.2.

Analogous to Figure 6, Figure 8 shows the dynamics of the pass-through and pass-around effect when we expand progressively the treatment window. The estimates underline the absence of a pass-around effect and a stable pass-through for pricing-to-market firms. For firms with a lower *TheilB*, the pass-around effect fades during 2015, while we observe an increase of  $\alpha$  over time. This is in line with the theoretical predictions about mean price changes as firms change their behavior progressively, as discussed in section 2.1 above.

**Figure 9:** Eurozone - CH price difference (2014, by nc8 products)

### 4.3 Sign of the ERPA

In the empirical analysis above we have found a positive exchange rate pass-around ( $\beta > 0$ ) which declines as we expand the treatment window. This is consistent with our model when  $p_S^{FOB} > p_E^{FOB}$ . It is therefore crucial to investigate whether the latter condition holds in the data. In order to check this inequality condition we estimate the price difference between Switzerland and all Eurozone countries in 2014 for each NC8 product separately.<sup>14</sup> For each product, we regress the log of firms' export prices,  $\ln p_{i,k,c,t}$ , on time fixed effects and a dummy that takes the value 1 if the firm exports to Switzerland. Figure 9 below shows the frequency distribution of the coefficients on these dummies. For a majority of the products (57.2%), French exporters charge a higher price on the Swiss market than in the Eurozone. We expect to observe a positive pass-around for these products. For the 30.6% products which do not show a significant difference, may be either products for which the  $p_S^{FOB}$  is not significantly different from  $p_E^{FOB}$ ) or ones where the proportion of single-price firms largely dominate. In the former case, we do not expect to see any ERPA, while in the latter we should see a significant one. Finally, the ERPA could be negative for those 12.2% of the products where the Swiss price is significantly lower than the Eurozone one.

Table 4 reports the estimations of the second model, equation (13), for products with negative and positive average price difference between the Eurozone and Switzerland, respectively. We again use our preferred sample, which retains exporters to Switzerland that invoice their shipments in Euros, exclude firms importing from Switzerland, as well as homogeneous products. In line with our theoretical expectations, it is clear that our benchmark results are driven by NC8 products where export prices (before the exchange rate shock) are higher in Switzerland than in the Euro area. A significant pass-around is visible for the latter only (see even rows of table 4).

<sup>14</sup>An alternative would be to rely on the 2014 price difference measured for each firm. But this would expose us to a risk of an endogeneity bias.

**Table 4:** Exchange rate pass-around for negative and positive price differences ( $p_S^{FOB} - p_E^{FOB}$ )

	Price Diff.	Destinations	Treatment period	Variable	Coefficient	Standard err.	Sample size

			Feb-Jun	$ERPA_{i,k,t} \times TheilB >p75$	0.007	(0.006)	

Notes: Significance levels: c:  $p < 0.1$ , b:  $p < 0.05$ , a:  $p < 0.01$ . Pre-treatment period: Jan.-Dec. 2014. Standard errors are clustered by destination-date and firm-product. The dependent variable is the log of export prices denominated in Euros. All regressions exclude firms that import from Switzerland in 2015 and homogeneous products (cf. Rauch's liberal product classification).

Products with  $(p_S^{FOB} - p_E^{FOB}) < 0$  show no significant pass-around, even for firms that have a high *TheilB* (cf. odd rows of table 4).

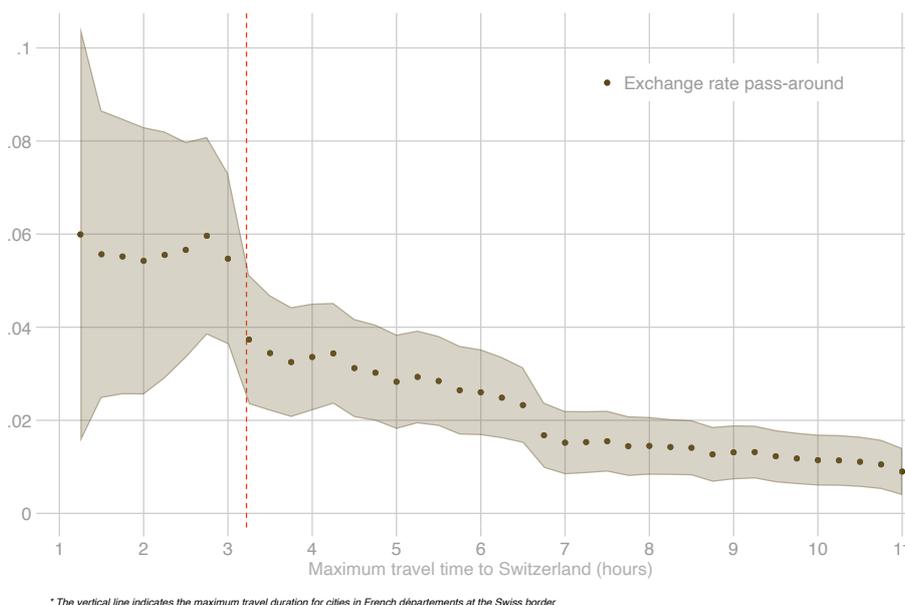

#### 4.4 Pass-around and trade costs to Switzerland

The ERPA in our model is sensitive to trade costs to the Swiss market and to its size as shown in equation (7). Since we focus on a single exchange rate shock, we cannot assess the role of the importer market size, as it is of course the same for all firms. Instead, we exploit the variance of distances between exporters to Switzerland to focus on the influence of trade costs on the magnitude of the pass-around. Simulations for the parameter values discussed above in relation to equation (7) predict a stronger ERPA for firms with smaller trade frictions to Switzerland.

To approximate trade costs for French firms to their Swiss consumers, we compute the road distance from each firm's municipality to Switzerland.<sup>15</sup> For firms with multiple establishments located in different cities, we retrain the shortest distance. Bilateral distances to Switzerland are computed as the weighted average of the closest road access between each French municipality to the geographical centroid of each the 26 Cantons of Switzerland.<sup>16</sup> Those distances are then weighted by the respective Cantons' share in total Swiss imports from France, similar to Hinz (2017).

<sup>15</sup>We only know the municipality of firms, not their exact geolocation. Since French cities are small and numerous ( $\approx 35,000$ ), we expect the error induced by the use of the coordinates of the municipality instead of those of the firm to be fairly small. As a comparison there are only about 11,000 in Germany.

<sup>16</sup>Distances are computed using the Open Source Routing Machine (Luxen and Vetter, 2011).

**Figure 10:** Exchange rate pass-around and travel time to Switzerland

Being equipped with a proxy for firm-specific trade costs to Switzerland, we run a series of estimates of equation (13), with different samples of firms defined by their maximum road time travel to Switzerland. We start with a set of firms located less than 1 hour and 15 minutes drive from the centre of Switzerland, then we enlarge the sample by steps of fifteen minutes, up to 11 hours (the few firms located in French municipalities that are more than 11 hours away from Switzerland are gathered in the last bin).

Estimates are shown graphically in Figure 10. We see clearly the expected negative relationship between the magnitude of the exchange rate pass-around and trade costs to reach the Swiss market. The closer the firms exposed to the exchange rate shock are to Switzerland, the more they increase their prices on the Eurozone markets after the Swiss Franc appreciation. Interestingly, we observe also a form of border effect. The vertical dotted line shows the maximum travel time between Switzerland and French cities located in departments bordering Switzerland.<sup>17</sup> It is clear that firms in these departments react more strongly than others.

## 5 Conclusion

In this paper, we document a new empirical fact: The exchange rate pass-around effect. French exporters, who were exposed to the sudden and unexpected appreciation of the Swiss Franc in January 2015 and had previously invoiced their exports to Switzerland in Euros, also saw a sudden change in export prices *to their Eurozone* customers. We rationalise this behavior with a stylized model of firms' export pricing strategy across markets — with pricing-to-market

<sup>17</sup>The French departments are administrative and geographical units corresponding to the NUTS3 of the European classification. The French continental territory is divided into 94 departments.

or single-pricing. We show that the proposed mechanism can explain the exchange rate pass-around effect, an incomplete exchange rate pass-through, and is directly compatible with other mechanisms that generate an incomplete pass-through, like a variable elasticity of demand and exchange rates in marginal costs. We test the model's predictions using monthly French firm-level customs data, confirming the existence of the exchange rate pass-around effect and quantifying its magnitude. While the estimated impact of the pass-around effect is economically modest and fades away over the longer term, its driving mechanism — a single-pricing strategy — generates an incomplete pass-through that has so far been unexplored in the literature.

Beyond the impact of the appreciation of the Swiss franc, we show that a non-negligible fraction of firms fails to price-to-market, at least in the short run. What the exchange rate pass-around reveals is that these rigidities deserve to be taken into consideration in order to understand and assess firms' reaction to price shocks in the global economy. It is also important to study the transmission of price changes between countries.

## A Appendix: The case of CHF invoices

In Table 5, we show estimates of our two models on the sample of treated firms made of those exporting to Switzerland in Swiss Franc. Comforting the stylized fact shown in Figure 3, the estimated pass-through is very large. During the first quarter following the exchange rate shock, exporters prices on the Swiss market, while converted in Euros, increased by 16.5%. This simply means that the pass-through is zero: French exporters invoicing in CHF did not change significantly their CHF prices and therefore absorbed all the currency shock. However, they gradually adjusted their prices over the course of 2015. From a zero pass-through during the first quarter, they moved to a roughly 50% pass-through by the end of 2015 (cf coefficient 0.072 on line 5 of Table 3. Contrasting with firms invoicing in Euros, there is no significant pass-around, in the short run, in the Eurozone for exporters invoicing in CHF. However, as the exporters adjust their prices on the Swiss market, we observe a rise of the pass-around, especially on the markets close to Switzerland (see lines 10 and 12).

**Table 5:** Exchange rate pass-through (ERPT) and pass-around (ERPA) for firms invoicing in CHF

## B Appendix: Robustness check

Our econometric specification for estimating the exchange rate pass-through and pass-around is a typical difference-in-differences study, based on a two-way fixed effects (TWFE) estimator. This estimator has been proved to produce misleading results, if the treatment is fuzzy or heterogeneous between groups and/or time.

At first glance, the setting of our difference-in-differences analysis is free of these concerns. The increase of the exchange rate is obviously the same for all firms; The intensity of treatment is homogeneous for all firms and (given the relative stability of the EUR-CHF exchange rate during 2015) does not vary much over time. We are not either in the case of a staggered treatment where different groups of units receive the treatment at different times (Goodman-Bacon, 2021). However, in practice, the treatment does not really apply simultaneously to all firm-destination pairs because firms do not export continuously to each destination. Firms' shipments are sporadic, and treated firms only effectively perceive the treatment in those months of 2015 in which they export. The severely unbalanced nature of our panel makes our design more complicated than it might seem, and a legitimate concern is that our two-way fixed effect estimators is not equivalent to a difference-in-differences and leads to non-robust conclusions (De Chaisemartin and D'Haultfoeuille, 2023).

It turns out the threat to our estimates is limited, though. Using the *twowayfweights* command (De Chaisemartin and D'Haultfoeuille, 2020) to estimate the weights attached to our benchmark

estimates of pass-through and pass-around effects (cf. columns 5 and 6 of Table 2), we find that the proportion of negative weights is very low. It is 0.42% for the pass-through estimate and 0.7% for the pass-around (with sum of negative weight of  $-1.335 \times 10^{-6}$  and  $-1.161 \times 10^{-5}$  respectively).

Nevertheless, we perform a simple robustness check to address this potential concern. We construct a balanced panel allowing to conduct an event study with a design that ensures the equivalence between the two-way fixed effects and the difference-in-difference estimator. We aggregate our monthly data by consecutive periods of three months: January-March 2014, April-June 2014, July-September 2014, October-December 2014, February-April 2015 and May-July 2015 (note that we therefore exclude January 2015). Then, we retain firm-product-country triads that are active both during the pre-treatment period and the first post-treatment period (February-April 2015). We obtain a balanced panel with a perfectly uniform treatment over the whole treated group. Table 6 confirms the results reported in section 4. The table reports the TWFE estimates on this balanced panel, along with results provided by the *did multiplegt* and the *csdid* estimators (cf. De Chaisemartin and D’Haultfoeuille (2020) and Callaway and Sant’Anna (2021), respectively).

*Notes:* Significance levels: c:  $p < 0.1$ , b:  $p < 0.05$ , a:  $p < 0.01$ . Pre-treatment period: Four quarters of 2014. Standard errors are clustered by destination-date and firm-product. The dependent variable is the log of export prices denominated in Euros. Monthly data are aggregated by quarters. The sample excludes importers from Switzerland, homogeneous products, firms that do not invoice their shipments to Switzerland in Euros.
